# Recursivity and the Estimation of Dynamic Games with Continuous Controls

João Granja Giuseppe Forte April 5, 2023

Click here for the latest version

#### **Abstract**

We revisit the estimation of dynamic games with continuous control variables, such as investments in R&D, quality, and capacity. We show how to use the recursive characterization of Markov Perfect Equilibria to develop estimators that exploit the structure of optimal policies. Our estimator resembles an indirect inference estimator, albeit in a two-step procedure that is common in the estimation of dynamic games. We use Monte Carlo experiments based on an empirically-relevant model of investment in R&D to compare the performance of our estimator with alternatives. We find that our estimator outperforms the commonly-used inequality estimator of Bajari, Benkard, and Levin (2007) and a naive implementation of an estimator based on recursive equilibrium conditions.

First draft: December 4, 2022.

### 1 Introduction

Many questions of interest to Industrial Organization economists involve firm choices that have persistent effects on market conditions. Such choices include investments in research and development, the choice of productive capacity, and the choice of product characteristics. Many other examples can be given. Decisions of this type are inherently dynamic and are often taken in industries with few firms. Therefore, their study necessitates the use of dynamic oligopoly models. Furthermore, many of these choices, such as the ones above, are naturally modeled as continuous variables.

This paper revisits the estimation of dynamic oligopoly models with continuous controls. The estimation of such models was made feasible by the seminal contribution of Bajari et al. (2007), henceforth BBL. Here we make the observation that the main estimator proposed by BBL does not use the full structure of the model, in that it does not exploit the structure of equilibrium policies. Exploiting this structure should lead to efficiency gains. We propose an estimator that does use the structure of equilibrium policies and conduct Monte Carlo exercises that compare its performance to different implementations of BBL and one other natural alternative in an empirically relevant model.

Our Monte Carlo exercises are based on Hashmi and van Biesebroeck (2016) – henceforth HvB. HvB propose and estimate an equilibrium model of innovation in the automobile industry. They are interested in the equilibrium relationship between market structure and innovation. In their model, firms engage in R&D – measured by firms' patenting activity – to increase product quality. The cost of R&D depends on the number of patents a firm files for and on an investment cost shock. We base our simulation exercises on the Hashmi and van Biesebroeck (2016) model because it underpins an actual empirical application, and thus accurately represents models used in practice.

The first step in our estimation routine consists of estimating policy functions and state transitions from the data. This is just as in BBL and estimators of dynamic games with discrete controls, such as the ones proposed by Aguirregabiria and Mira (2007), Pakes, Ostrovsky, and Berry (2007), and Pesendorfer and Schmidt-Dengler (2008). We depart from BBL in the second step. We use the estimated policy functions and state transitions to form and solve the maximization problem in the right-hand-side of firms' Bellman equations. We do so at the states observed in the data and randomly drawn investment cost shocks. We then project these predicted investment levels onto the space spanned by

the basis functions in the empirical policy. Finally, we minimize a measure of the distance between the estimated policy function coefficients and those implied by the projection step. Therefore, our estimator combines elements of the two-step estimators that sprung from Hotz and Miller (1993) with Indirect Inference estimators à la Gourieroux, Monfort, and Renault (1993).

The intuition behind our estimator is simple. Under the maintained assumption that the estimated policies constitute an equilibrium, solving the right-hand-side of firms' Bellman equations must return the same policy. It is therefore also natural to consider an estimator that directly compares the estimated policy and the one implied by firms' Bellman equations. This would be the continuous-control analog of the estimator proposed by Pesendorfer and Schmidt-Dengler (2008). We thus include this estimator in our Monte Carlo experiments.

We find that our estimator has desirable properties. In our Monte Carlo exercise, its finite-sample bias is small and the estimator is precise. We compare it to two implementations of BBL. The first one uses the policy deviations employed by HvB. The second one forms deviations at random based on the estimated policy function. In contrast to our estimator, we find that both implementations of BBL have very substantial finite sample bias. In fact, the estimates are orders of magnitude away from the true parameters. We relate these findings to the shape of the objective functions that define each estimator. While our estimator's objective function attains its minimum close to the truth and has large curvature, we find the BBL objective to be flat around the true parameters. When we consider the estimator that directly compares the estimated and model-implied policies, we find it to have poor properties.

Our estimator enjoys other benefits relative to BBL. First, it does not require the econometrician to choose policy deviations. This is an advantage, as the performance of the BBL estimator may very well depend on the deviations chosen by the analyst. This concern is substantiated by the different performance of the two BBL alternatives we consider. Second, we find that our estimator is faster to compute. Though our estimator adds the cost of solving (static) optimization problems multiple times, it does away with the simulation in BBL – by far the most expensive part of the algorithm. We find that the savings trump the costs. Our estimator takes about one third of the BBL run time.

It would be remiss of us not to remind the reader that Bajari et al. (2007) do propose a second estimator based on solving for firms' optimal policies. Nevertheless, the empirical literature seems to have converged to using the estimator that they discuss at greater length, based on value function inequalities.

A number of applications, including very recent ones, use the inequality estimator. These include Ryan (2012), Hashmi and van Biesebroeck (2016), Fowlie, Reguant, and Ryan (2016), and Liu and Siebert (2022). We are not aware of any empirical paper estimating a dynamic game with continuous controls using an estimator based on firms' Bellman equations.

The paper most closely related to our is Srisuma (2013). Srisuma also observes that the BBL inequalities may fail to identify the structural parameters and proposes an estimator that makes use of agents' optimization problems in a two-step procedure. The main distinctions between our approach and Srisuma's are practical. Srisuma's estimator is based on minimizing a distance between the observed conditional distributions of agents' actions and the one implied by agents' (pseudo) maximization problems. This has practical drawbacks. The estimation of the implied distribution is done by simulation. A precise estimator may require the solution of many (static) optimization problems – many more than what we have to solve. Moreover, the implied distribution is discontinuous in the structural parameters. These two features make the estimator potentially costly and difficult to compute for the models that practitioners take to data. Indeed, the Monte Carlo simulations in Srisuma (2013) are based on simple static models.

We therefore view our contributions as threefold. First, we show that estimators based on recursive equilibrium conditions can outperform the inequality-based estimators applied in the empirical literature by a wide margin. Second, we provide implementation details for an estimator based on recursive equilibrium conditions in an empirically relevant setting, including shocks to firms' marginal costs of investment. Third, we show that a natural alternative estimator known to perform well in discrete control settings can have poor performance in continuous-control environments. Along the way we also show how one can do away with value function simulation and can instead solve for these objects, thus eliminating simulation error.

The rest of the paper is organized as follows. In section 2 we discuss the Hashmi and van Biesebroeck (2016) model. In section 3 we discuss estimators based on recursive equilibrium conditions. In section 4 we provide a brief review of the main BBL estimator. In section 5 we discuss the results of our Monte Carlo exercises. Finally, in section 6 we offer concluding remarks.

### 2 The Economic Model

We base our comparison of estimators on the model of innovation in the automobile industry of Hashmi and van Biesebroeck (2016). As in all dynamic games following the Ericson and Pakes (1995) framework, there is a static part to the model and a dynamic one. In the static part, firms play a Nash-Bertrand pricing game, given demand and marginal cost functions. In the dynamic part, firms invest in R&D. Investments in R&D affect the quality of firms' products, which in turn affects demand and production costs. There is no entry or exit.<sup>1</sup>

The timing of the model is as follows. Firms start the period with given quality levels. They simultaneously set prices, which determine the quantity sold and flow profits. They then privately observe a shock to their investment cost. Next, firms simultaneously decide how much to invest and pay the associated costs. Firm investments affect the distribution of the quality of their products in the beginning of the following period. Firms' random quality levels realize before the start of the new period.

We discuss the static and dynamic parts of the model in turn.

### 2.1 Price Competition Given Demand and Costs

There are N single-product firms in the market, indexed by  $j=1,2,\ldots,N$ .<sup>2</sup> There is a measure M of consumers in the market, and consumers are indexed by i. If consumer i buys firm j's product, she obtains conditional indirect utility

$$u_{ij} = \alpha p_j + \xi_j + \varepsilon_{ij} ,$$

where  $\alpha$  is the marginal utility of income,  $p_j$  is the price of good j,  $\xi_j$  is a quality index and  $\varepsilon_{ij}$  is a random shock that follows a Type 1 Extreme Value distribution. There is also an outside option, indexed by j=0. Its non-random utility is normalized to zero,  $u_{i0}=\varepsilon_{i0}$ .

As is well-known, this specification of utility yields the market share func-

<sup>&</sup>lt;sup>1</sup>Entry and exit are not observed in the Hashmi and van Biesebroeck (2016) data, which is why those decisions are not included in their model. For our purposes, this simplifies the exposition and allows us to focus on the continuous control, which is our main interest.

<sup>&</sup>lt;sup>2</sup>Hashmi and van Biesebroeck (2016) estimate a demand model that accounts for the many products sold by automakers. When setting up their dynamic game of innovation, they (heuristically) aggregate that model to the firm level. This aggregation makes the dynamic model tractable. Here, as our focus is on methods for estimating the dynamic parameters of the model, we start from a model of single-product firms.

tion

$$s_j(\boldsymbol{p};\boldsymbol{\xi}) = \frac{\exp(\alpha p_j + \xi_j)}{1 + \sum_k \exp(\alpha p_k + \xi_k)}, \quad j = 1,\dots, N$$

where  $p = (p_1, ..., p_N)$  and  $\xi = (\xi_1, ..., \xi_N)$ . Prices are modeled as the outcome of a Bertrand game. Firm j solves

$$\max_{p_j} \pi_j(p_j; \mathbf{p}_{-j}, \mathbf{\xi}) := (p_j - \mu(\xi_j)) s_j(\mathbf{p}; \mathbf{\xi}) ,$$

where  $\mu_j(\xi_j)$  is firm j's constant marginal cost of production, which depends on its quality level, and firm j takes  $\boldsymbol{p}_{-j} = (p_1, \dots, p_{j-1}, p_{j+1}, \dots, p_N)$  as given. The marginal cost function is specified as

$$\mu(\xi_j) = \exp(\theta_{c1} + \theta_{c2}\xi_j) .$$

We know from Caplin and Nalebuff (1991) that this pricing game has a unique equilibrium. Moreover, the equilibrium price vector,  $\mathbf{p}^*(\boldsymbol{\xi}) = (p_1^*(\boldsymbol{\xi}), \dots, p_N^*(\boldsymbol{\xi}))$ , must satisfy the system of first-order conditions:

$$\alpha(1 - s_j(\mathbf{p}^*; \boldsymbol{\xi}))(p_j^* - \mu_j(\xi_j)) + 1 = 0, \quad j = 1, \dots, J$$
 (1)

The equilibrium  $p^*(\xi)$  induces profits  $\pi_j(\xi) := [p_j^*(\xi) - \mu(\xi_j)]s_j(p^*(\xi), \xi)$ .

### 2.2 Investment in R&D

### 2.2.1 Quality Transitions

Firms invest to affect the quality of their product in the next period. Firms' qualities belong to the set  $\Xi = \{\xi_{\min}, \xi_{\min} + \delta, \dots, \xi_{\max} - \delta, \xi_{\max}\}$ . If  $\xi_{\min} < \xi < \xi_{\max}$ , then  $\xi$  can decrease by  $\delta$ , stay unchanged, or increase by  $\delta$ . These transition probabilities are parameterized as

$$P(\xi'|\xi,x) = \begin{cases} \theta_{t1}[1 - \text{up}(\xi,x)] & \text{if } \xi' = \xi - \delta \\ 1 - \theta_{t1} - \text{up}(\xi,x)(1 - 2\theta_{t1}) & \text{if } \xi' = \xi \\ (1 - \theta_{t1})\text{up}(\xi,x) & \text{if } \xi' = \xi + \delta \\ 0 & \text{otherwise} \end{cases}$$
(2)

where

$$\operatorname{up}(\xi, x) = e^{-e^{-\theta_{t2}\log(x+1) - \theta_{t3}\xi - \theta_{t4}\xi^2}}$$
.

In the expressions above x denotes investment in R&D and  $\theta_t = (\theta_{t1}, \theta_{t2}, \theta_{t3}, \theta_{t4})$  is a vector of parameters governing the transition probabilities. To respect the finiteness of  $\Xi$ , we adjust these probabilities at the maximum and minimum values of  $\Xi$ . When  $\xi = \xi_{min}$  we set  $P(\xi|\xi,x)$  equal to the sum of the first two cases in equation 2. When  $\xi = \xi_{max}$  we set  $P(\xi|\xi,x)$  equal to the sum of the second and third cases in equation 2.

The interpretation of this specification is that the quality of a product is subject to a positive and a negative shock. One can think of the negative shock as capturing improvements in the outside option. The positive shock captures successes in the R&D process. The negative shock occurs with probability  $\theta_{t1}$ , whereas the positive shock occurs with probability up( $\xi_j$ , x). Quality falls when the product's quality experiences a negative shock without an offsetting positive shock. It grows when quality experiences a positive shock unmatched by a negative shock. In all other cases, quality remains the same. Positive and negative shocks are independent across firms, conditional on  $\xi$  and x.

The probability of an improvement in the outside option is independent of firms' qualities and investments. The reasoning is that the outside option is outside of the focal market, and the process driving its quality is unresponsive to the conditions of the market being analyzed. The probability of an R&D success, however, does depend on a firm's investment and quality, but not on its competitors'. In particular, if  $\theta_{t2}>0$  and  $\theta_{t3}<0$ , the specification of  $\operatorname{up}(\xi_j,x)$  implies that the probability of success is increasing in own investment and decreasing in own quality. This last effect captures the notion that it is harder to improve on a high-quality product. The sign of  $\theta_{t4}$  determines whether an increase in quality reduces the probability of success at an increasing or decreasing rate.

#### 2.2.2 The Firm's Problem

Firms choose their investment to maximize their present-discounted stream of profits. They trade-off better future prospects for the quality of their product against the immediate cost of investment,  $c(x, \nu)$ . This cost depends on the level of investment x and on a privately observed investment cost shock,  $\nu$ . The cost shock is assumed to be iid across firms and follows a standard normal distribu-

<sup>&</sup>lt;sup>3</sup>The independence of negative shocks across firms is at odds with its interpretation as capturing improvements in the outside option. We make this assumption for two reasons. First, it simplifies the exposition somewhat. Second, despite stating otherwise (p. 200), HvB seem to treat the negative shocks as independent at times (see their discussion of simulation in p. 201).

tion. We focus throughout on Markov Perfect Equilibria. Firms' state variables are the vector of qualities in the market,  $\xi$ , and their privately observed investment cost shock  $\nu$ . Firm behaviour depends only on the state variables. Denote firm j's policy function by  $\sigma_j(\xi,\nu)$  and let  $\sigma=(\sigma_1,\ldots,\sigma_N)$ . Firm j's problem can then be recursively represented as

$$V_{j}(\xi_{j}, \boldsymbol{\xi}_{-j}, \nu) = \max_{x \in \mathbb{R}_{+}} \left\{ \pi(\xi_{j}, \boldsymbol{\xi}_{-j}) - c(x, \nu) + \beta \mathbb{E}_{\boldsymbol{\sigma}_{-j}} \left[ V_{j}(\xi'_{j}, \boldsymbol{\xi'}_{-j}, \nu' | \xi_{j}, \boldsymbol{\xi}_{-j}, x) \right] \right\}$$
(3)

where

$$\mathbb{E}_{\boldsymbol{\sigma}_{-j}}\left[V_{j}(\xi_{j}',\boldsymbol{\xi}_{-j}',\nu')|\xi_{j},\boldsymbol{\xi}_{-j},x\right] = \sum_{\boldsymbol{\xi}_{j}'} \sum_{\boldsymbol{\xi}_{-j}'} \int_{\nu} V_{j}(\xi_{j}',\boldsymbol{\xi}_{-j}',\nu') dF(\nu') P_{-j}(\boldsymbol{\xi}_{-j}'|\boldsymbol{\xi};\boldsymbol{\sigma}_{-j}) P_{j}(\xi_{j}'|\xi_{j},x)$$

$$\tag{4}$$

and

$$P_{-j}(\boldsymbol{\xi}'_{-j}|\boldsymbol{\xi};\boldsymbol{\sigma}_{-j}) = \prod_{k \neq j} P(\xi'_k|\boldsymbol{\xi};\sigma_k) = \prod_{k \neq j} \int_{\nu_k} P(\xi'_k|\xi_k,\sigma_k(\boldsymbol{\xi},\nu_k)) dF(\nu_k) . \tag{5}$$

In this last expression, the terms  $P(\xi'_k|\xi_k, \sigma_k(\xi, \nu_k))$  are derived from the quality transition model discussed in section 2.2.1.

We proceed as in Doraszelski and Pakes (2007). Define

$$EV_j(\boldsymbol{\xi}) := \int_{\nu_j} V_j(\xi_j, \boldsymbol{\xi}_{-j}, \nu) dF(\nu)$$

and

$$W(\xi_j'|\boldsymbol{\xi};\boldsymbol{\sigma}_{-j}) := \sum_{\boldsymbol{\xi}_{-j}'} EV(\xi_j',\boldsymbol{\xi}_{-j}') P_{-j}(\boldsymbol{\xi}_{-j}'|\boldsymbol{\xi};\boldsymbol{\sigma}_{-j}) .$$

 $EV(\xi)$  is the expected present-discounted stream of profits when the vector of qualities is  $\xi$ . The object  $W(\xi'_j|\xi;\sigma_{-j})$  is the expected value of landing on quality  $\xi'_j$  starting from the vector of qualities  $\xi$ . With these definitions we can write

$$\mathbb{E}_{\boldsymbol{\sigma}_{-j}}\left[V_j(\xi_j',\boldsymbol{\xi}_{-j}',\nu')|\xi_j,\boldsymbol{\xi}_{-j},x\right] = \sum_{\boldsymbol{\xi}_j'} W(\xi_j'|\boldsymbol{\xi};\boldsymbol{\sigma}_{-j})P_j(\xi_j'|\xi_j,x)$$

The first-order condition of the maximization problem on the right hand side of the Bellman equation is then

$$\frac{\partial c(x,\nu)}{\partial x} = \beta \sum_{\boldsymbol{\xi}_{j}'} W(\boldsymbol{\xi}_{j}'|\boldsymbol{\xi};\boldsymbol{\sigma}_{-j}) \frac{\partial P_{j}(\boldsymbol{\xi}_{j}'|\boldsymbol{\xi}_{j},x)}{\partial x}$$
(6)

At the optimum level of investment, given  $\xi$  and  $\nu$ , the firm equates the marginal cost of investment to its marginal benefit. The marginal cost of investment is an exogenous object. The marginal benefit of investment depends on how investment changes the distribution over quality levels in the following period. It also depends on the value of starting the following period with different levels of quality,  $\xi'_j$ . Moreover, these future values take into account the current quality-state. For instance, the gain in present-discounted profits from an increase in quality may be smaller if a firm's competitors all have substantially lower quality, relative to a case in which their qualities are similar to the focal firm's.

It is worth noting for future reference that condition 6 can also be written as

$$\frac{\partial c(x,\nu)}{\partial x} = \beta \frac{\partial \operatorname{up}(\xi_j, x)}{\partial x} \times \Delta W(\xi; \sigma_{-j})$$
(7)

where  $\Delta W(\boldsymbol{\xi}; \boldsymbol{\sigma}_{-j})$  is given by

$$(1 - \theta_{t1})[W(\xi_j + \delta | \boldsymbol{\xi}; \boldsymbol{\sigma}_{-j}) - W(\xi_j | \boldsymbol{\xi}; \boldsymbol{\sigma}_{-j})] + \theta_{t1}[W(\xi_j | \boldsymbol{\xi}; \boldsymbol{\sigma}_{-j}) - W(\xi_j - \delta | \boldsymbol{\xi}; \boldsymbol{\sigma}_{-j})].$$

Fix a  $\boldsymbol{\xi}$  and suppose that there exists  $\nu$  such that  $\sigma(\boldsymbol{\xi},\nu)>0$ . Assume further that  $\partial_x c(x,\nu)>0$  for all  $(x,\nu)$ .<sup>4</sup> Because  $\sigma(\boldsymbol{\xi},\nu)>0$ , the first-order condition must hold with equality – i.e., equation 7 must hold. Therefore, it must be the case that  $\Delta W(\boldsymbol{\xi};\boldsymbol{\sigma}_{-j})>0$ . This has two implications. First, this condition is a restriction on the equilibrium value function and by itself provides restrictions on the structural parameters. Second, this implies that the firm's problem is globally concave at that  $\boldsymbol{\xi}$  for *all*  $\nu$ . We will return to these observations when we discuss our estimator.

In our numerical exercise, we parameterize the investment cost function as

$$c(x,\nu) = \theta_{x1}x + \theta_{x2}x^2 + \theta_{x3}\nu x .$$

This is as in HvB, except that they also include a cubic term.

<sup>&</sup>lt;sup>4</sup>This fails to hold in our specification due to the full support of  $\nu$ . However, in our parameterization the probability that this condition fails is small. We retain the normality assumption for convenience.

### 2.3 Equilibrium and Computation

We focus on symmetric Markov Perfect Equilibria, i.e.,  $\sigma_j(\boldsymbol{\xi}, \nu) = \sigma(\boldsymbol{\xi}, \nu)$  for  $j=1,\ldots,N$ . As shown by equations (4) and (5), the expectation in the Bellman equation (3) depends on  $\sigma(\cdot,\cdot)$ . Therefore, one can think of equation (3) as defining an operator that maps policy and value functions into themselves:  $T:\Sigma\times\mathcal{V}\to\Sigma\times\mathcal{V}$ , where  $\Sigma$  denotes the set of feasible policy functions and  $\mathcal{V}$  the set of feasible value functions. This operators returns a firm's best-response to its competitors all playing a given strategy  $\sigma$  (given V). A strategy profile  $(\sigma,\ldots,\sigma)$  is a symmetric Markov Perfect Equilibrium if and only if  $(\sigma,V_\sigma)$  is a fixed-point of T, where  $V_\sigma$  is the expected present-discounted stream of profits when all firms play the strategy  $\sigma$ .

This representation underpins the method we employ to solve for Markov Perfect Equilibria. We start with a guess for value and policy functions. With the policy functions we can compute the implied transition probabilities for firms' qualities. Having transition probabilities and the guess for the value function, we can compute the terms  $W(\xi_i'|\boldsymbol{\xi};\boldsymbol{\sigma}_{-i})$ . This allows us to solve firms' first-order conditions, which yields new guesses for policy and value functions. We iterate on these steps until both value and policy functions converge. This is, of course, simply the Pakes and McGuire (1994) algorithm. As in Pakes and McGuire (1994), note that the symmetry assumption implies that the state  $\xi =$  $(\xi_i, \boldsymbol{\xi}_{-i})$  is equivalent to  $\boldsymbol{\xi} = (\xi_i, \pi(\boldsymbol{\xi}_{-i}))$  for any permutation  $\pi$  of competitors' qualities. Therefore, we need not compute value and policy functions at each  $\xi$ , but only at a member of the equivalence class. In particular, we retain only  $\xi$ 's such that competitors' qualities are increasing in their index, i.e.,  $\xi_2 \leq \ldots \leq \xi_N$ . As shown in Pakes and McGuire (1994), this implies that the state space grows in the number of firms not exponentially, but rather as a polynomial of order  $|\Xi|$ . In our numerical examples below, this reduces the cardinality of the state space from just under 760,000 to 45,900.<sup>5</sup>

$$V(\boldsymbol{\xi}, \nu; \sigma) = \pi(\boldsymbol{\xi}) - c(\sigma(\boldsymbol{\xi}, \nu), \nu) + \beta \mathbb{E}_{\sigma} \left[ V(\boldsymbol{\xi'}, \nu') | \boldsymbol{\xi}, \boldsymbol{\sigma}(\boldsymbol{\xi}, \nu) \right] .$$

Next, solve the right-hand-side of equation 3 to obtain  $\tilde{T}\sigma$ . A symmetric strategy profile  $(\sigma, \ldots, \sigma)$  is a symmetric MPE if and only if it is a fixed point of  $\tilde{T}$ . One can thus solve for an MPE by iterating on these two steps.

<sup>&</sup>lt;sup>5</sup>One can alternatively view equation 3 as an operator  $\tilde{T}: \Sigma \to \Sigma$  defined in two steps. First, compute the value function implied by  $\sigma$ , i.e.,

# 3 Estimators Based on the Recursive Equilibrium Conditions

In this section we discuss estimators based on the Bellman Equation (3). Firstly, by exploiting (3), these estimators make use of the structure of optimal policy functions, i.e., the fact that optimal policy functions must solve the right-hand side of the Bellman equation. The algorithm proposed in BBL does not make use of this feature. Secondly, the estimators we propose free the researcher from having to commit to a choice of policy deviations, which in practice affect the performance of the BBL estimator. Our estimator will therefore have econometric and practical advantages relative to BBL.<sup>6</sup>

Suppose that we have estimates of the ex-ante value function  $EV(\xi;\theta):=\int V(\xi,\nu;\sigma,\sigma,\theta)dF(\nu)$ . Denote these estimates by  $\widehat{EV}(\xi;\theta)$ . These estimates could be obtained by forward simulation, as in Bajari et al. (2007). We discuss an alternative below, but for now let us focus on the main point of difference between our estimator and BBL. Suppose that we also have an estimate of  $P(\xi'_j \mid \xi_j, x)$ . This could be estimated non-parametrically; in our Monte Carlo experiments we estimate the parametric model in (2). Using  $\widehat{EV}(\xi;\theta)$  and  $\widehat{P}(\xi'_j \mid \xi_j, x)$ , we can setup and solve the right-hand side of the Bellman Equation (3):

$$\max_{x \in \mathbb{R}_{+}} \left\{ \pi(\xi_{j}, \boldsymbol{\xi}_{-j}) - c(x, \nu; \theta) + \beta \mathbb{E}_{\hat{\sigma}} \left[ \widehat{EV}(\xi'_{j}, \boldsymbol{\xi'}_{-j}; \theta) | \xi_{j}, \boldsymbol{\xi}_{-j}, x \right] \right\}.$$
 (8)

Solving problem (8) at some  $(\xi, \nu)$  yields a new predicted level of investment at that state, which depends on the parameters  $\theta$ . We denote these predicted investment levels by  $T_{\theta}(\xi_i, \nu_i; \widehat{EV(\theta)})$ .

We can consider different estimators of  $\theta$  that use the predicted levels of investment  $T_{\theta}(\boldsymbol{\xi}_{i}, \nu_{i}; \widehat{EV(\theta)})$ . Our preferred approach is akin to indirect inference. We estimate  $\mathbb{E}[\sigma(\boldsymbol{\xi}, \nu) \mid \boldsymbol{\xi}]$  by projecting observed levels of investment onto a set of basis functions  $\{\Psi_{k}\}_{k=1}^{B}$ :

$$x_i = \sum_{k=1}^{B} \gamma_k \Psi_k(\boldsymbol{\xi_i}) + \eta_i \tag{9}$$

<sup>&</sup>lt;sup>6</sup>Another important point of comparison is computational cost. As will become clear as we discuss our estimator, there is a trade-off. Our estimator will require simulating or solving for value functions only once. The Bajari et al. (2007) estimator requires doing so for all pairs  $(\sigma',\sigma)$  that enter the objective function. However, our estimator requires solving at least as many static optimization problems as observations in the data. In the Monte Carlo experiments we perform in section 5 this computational trade-off is resolved in BBL's favor.

Let  $\hat{\gamma} := \left[\hat{\gamma}_1, \dots, \hat{\gamma}_B, \hat{S}_\eta\right]$ , where  $\hat{S}_\eta = (N-B)^{-1} \sum_{i=1}^N (x_i - \sum_{k=1}^B \hat{\gamma}_k \Psi_k(\boldsymbol{\xi_i}))$  is an estimate of the standard deviation of  $\eta_i$ . We solve the problem (8) for each  $\boldsymbol{\xi}$  observed in the data and a randomly drawn  $\nu \sim N(0,1)$ , which yields  $\{T_\theta(\boldsymbol{\xi}_i, \nu_i; \widehat{EV(\theta)})\}_{i=1}^N$ . Next, we estimate

$$T_{\theta}(\boldsymbol{\xi}_{i}, \nu_{i}; \widehat{EV(\theta)}) = \sum_{k=1}^{B} \lambda_{k} \Psi_{k}(\boldsymbol{\xi}_{i}) + \zeta_{i} , \qquad (10)$$

which yields  $\hat{\boldsymbol{\lambda}}(\theta;\widehat{EV(\theta)}) := \left[\hat{\lambda}_1(\theta;\widehat{EV(\theta)}),\dots,\hat{\lambda}_B(\theta;\widehat{EV(\theta)}),\hat{S}_{\zeta}(\theta;\widehat{EV(\theta)})\right]$ . Finally, for some positive-definite weight matrix  $\boldsymbol{W}$ , we define our estimator to be<sup>7</sup>

$$\hat{\theta}_{II} := \arg\min_{\theta} Q(\theta; \boldsymbol{W}, \widehat{EV(\theta)}) = \left[\hat{\boldsymbol{\lambda}}(\theta; \widehat{EV(\theta)}) - \hat{\gamma}\right]' \boldsymbol{W} \left[\hat{\boldsymbol{\lambda}}(\theta; \widehat{EV(\theta)}) - \hat{\gamma}\right] . \tag{11}$$

The intuition for the estimator above is the following. If the policy observed in the data,  $\hat{\sigma}$ , is a Markov Perfect Equilibrium, it must satisfy the recursive equilibrium conditions (3). Therefore, if we solve the right-hand side of the Bellman Equation using transitions and value functions implied by  $\hat{\sigma}$ , we must obtain  $\hat{\sigma}$  back. One could try to estimate the structural parameters by matching  $T_{\theta}(\cdot;\widehat{EV(\theta)})$  and  $\hat{\sigma}$ . Srisuma (2013) proposes matching the conditional distribution of investment observed in the data and that implied by  $T_{\theta}(\cdot;\widehat{EV(\theta)})$ , which is a closely related idea. Unfortunately, computing the conditional distribution of investment implied by  $T_{\theta}(\cdot;\widehat{EV(\theta)})$  is computationally very costly. We instead match features of those distributions. We find that the resulting estimators are sufficiently cheap to compute and perform better than existing alternatives.

### 3.1 Estimating EV

Let  $EV(\boldsymbol{\xi}) = \int V(\boldsymbol{\xi}, \nu) dF(\nu)$  denote the ex-ante value function and let  $\boldsymbol{EV} = [EV(\boldsymbol{\xi}_1), \dots, EV(\boldsymbol{\xi}_{|\Xi|})]$  be a vector stacking the value function at each state in the state space.<sup>8</sup> We show in appendix A that  $\boldsymbol{EV}$  satisfies <sup>9</sup>

$$EV = W(\pi, \sigma)[1, -\theta'_x]' + \beta M(P)EV$$
(12)

<sup>&</sup>lt;sup>7</sup>As always, having the analytical gradient of the objective (11) significantly accelerates the calculation of the optimum. In appendix B we perform the relevant calculations.

<sup>&</sup>lt;sup>8</sup>More precisely, at each element of the set of equivalence classes induced by the symmetry restrictions.

<sup>&</sup>lt;sup>9</sup>Related calculations appear e.g. in Jofre-Bonet and Pesendorfer (2003).

or

$$EV(\sigma, P; \boldsymbol{\pi}, \beta, \boldsymbol{\theta}_x) = [I - \beta \boldsymbol{M}(P)]^{-1} \boldsymbol{W}(\boldsymbol{\pi}, \sigma) [1, -\boldsymbol{\theta}_x']', \qquad (13)$$

where the  $\xi$ -th row of  $W(\pi, \sigma)$ , which we denote  $W(\xi; \pi, \sigma)$ , is a vector of the expected flow-profit covariates at state  $\xi$  and M(P) is the transition matrix implied by the policy function  $\sigma$ . Specifically,

$$\boldsymbol{W}(\boldsymbol{\xi}; \boldsymbol{\pi}, \sigma) = \begin{bmatrix} \pi(\boldsymbol{\xi}) & \mathbb{E}[\sigma(\boldsymbol{\xi}, \nu) | \boldsymbol{\xi}] & \mathbb{E}[\sigma(\boldsymbol{\xi}, \nu)^2 | \boldsymbol{\xi}] & \mathbb{E}[\sigma(\boldsymbol{\xi}, \nu) \nu | \boldsymbol{\xi}] \end{bmatrix}, \quad (14)$$

and

$$M(\mathbf{P}) = \begin{bmatrix} \mathbb{P}(\boldsymbol{\xi}_1 | \boldsymbol{\xi}_1) & \dots & \mathbb{P}(\boldsymbol{\xi}_{|\Xi|} | \boldsymbol{\xi}_1) \\ \vdots & \ddots & \vdots \\ \mathbb{P}(\boldsymbol{\xi}_1 | \boldsymbol{\xi}_{|\Xi|}) & \dots & \mathbb{P}(\boldsymbol{\xi}_{|\Xi|} | \boldsymbol{\xi}_{|\Xi|}) \end{bmatrix}$$
(15)

where

$$\mathbb{P}(\boldsymbol{\xi}'|\boldsymbol{\xi}) = \prod_{j=1}^{N} \mathbb{P}(\xi_j' \mid \boldsymbol{\xi}) = \prod_{j=1}^{N} \int \mathbb{P}(\xi_j' \mid \xi_j, \sigma(\boldsymbol{\xi}, \nu)) dF(\nu) . \tag{16}$$

Observe that although we write  $W(\pi, \sigma)$ , W does not depend on the policy function per se, but only on conditional expectations of functions of investment and the covariance between the policy function and the investment cost shock.

Equations (13) to (16) imply that we can estimate EV by estimating the conditional expectations in (14) and  $\mathbb{P}(\xi_j' \mid \boldsymbol{\xi})$ . The objects  $\mathbb{E}[\sigma(\boldsymbol{\xi}, \nu) \mid \boldsymbol{\xi}]$ ,  $\mathbb{E}[\sigma(\boldsymbol{\xi}, \nu)^2 \mid \boldsymbol{\xi}]$ , and  $P(\xi_j' \mid \boldsymbol{\xi})$  are readily identified from the data. The BBL argument for identification of the policy function implies, in the case in which  $\sigma(\boldsymbol{\xi}, \nu)$  is decreasing in  $\nu$ , that

$$\sigma(\xi, \nu) = F_X^{-1}(1 - \Phi(\nu) \mid \xi) , \qquad (17)$$

where  $F_X(x \mid \boldsymbol{\xi})$  is the distribution of investment conditional on  $\boldsymbol{\xi}$ , which is identified, and  $\Phi$  is the standard normal cumulative distribution function. That is, the policy function is identified as the quantiles of the conditional distribution of investment. Using this,  $\mathbb{E}[\sigma(\boldsymbol{\xi},\nu)\nu\mid\boldsymbol{\xi}]$  can be approximated by Gauss Hermite quadrature as  $\pi^{-1/2}\sum_{i=1}^N \omega_i F_X^{-1}(1-\Phi(\sqrt{2}\nu_i)\mid\boldsymbol{\xi})\sqrt{2}\nu_i$ , for judiciously chosen weights  $\omega_i$  and nodes  $\nu_i$ . Therefore, all that is needed to estimate  $\mathbb{E}[\sigma(\boldsymbol{\xi},\nu)\nu\mid\boldsymbol{\xi}]$  is identified in the data. Note however that in principle the above argument requires estimating investment quantiles at each element of  $\boldsymbol{\xi}$  – a daunting task if many such elements are seldom observed. As an alternative, we propose approximating  $F_X^{-1}(1-\Phi(x)\mid\boldsymbol{\xi})$  by quantile regression of investment on features of  $\boldsymbol{\xi}$ .

### 4 A Brief Review of BBL

In this section we briefly review the main estimator proposed by Bajari et al. (2007), which is the main point of comparison for the estimator we propose in Section 3.

The expected present-discounted stream of profits of a firm when it plays a strategy  $\sigma_i$  and all its competitors play the strategy  $\sigma$  is given by

$$V(\boldsymbol{\xi}, \nu; \sigma_j, \sigma) = \mathbb{E}\left\{\sum_{t=0}^{\infty} \beta^t \left[\pi(\xi_{jt}, \boldsymbol{\xi}_{-j,t}) - c(\sigma_j(\boldsymbol{\xi}_t, \nu_{jt}), \nu_{jt})\right] \middle| \boldsymbol{\xi}_0 = \boldsymbol{\xi}, \nu_{j0} = \nu\right\}$$

where, letting  $P(\xi, x)$  denote the probability mass function defined in Equation (2),  $\xi_{j,t+1} \sim P(\xi_{j,t}, \sigma_j(\xi_t, \nu_{jt}))$  and for  $k \neq j$ ,  $\xi_{k,t+1} \sim P(\xi_{k,t}, \sigma(\xi_t, \nu_{kt}))$ .

By definition, a symmetric strategy profile  $(\sigma,\ldots,\sigma)$  is a Markov Perfect Equilibrium if

$$V(\boldsymbol{\xi}, \nu; \sigma, \sigma) \ge V(\boldsymbol{\xi}, \nu; \sigma', \sigma) \quad \forall \, \boldsymbol{\xi}, \nu, \sigma' \tag{18}$$

Bajari et al. (2007) base their estimator on the equilibrium conditions (18). Define

$$g(\boldsymbol{\xi}, \nu, \sigma'; \sigma, \theta) := V(\boldsymbol{\xi}, \nu; \sigma, \sigma, \theta) - V(\boldsymbol{\xi}, \nu; \sigma', \sigma, \theta)$$

where we have made the dependence on the structural parameters  $\theta$  explicit. Let H be a distribution over the space of tuples of the form  $(\xi, \nu, \sigma')$ . Define

$$Q(\theta, \sigma) := \int \left( \min \left\{ g(\boldsymbol{\xi}, \nu, \sigma'; \sigma, \theta), 0 \right\} \right)^2 dH(\boldsymbol{\xi}, \nu, \sigma')$$
(19)

Let  $\mathcal{E}(\theta)$  be the set of MPE when the parameters of the model are given by  $\theta$  and let  $\theta_0$  denote the true parameter value. If  $\sigma \in \mathcal{E}(\theta_0)$ , the equilibrium conditions above imply that  $Q(\theta_0, \sigma) = 0$ .

**Assumption 1** (ID). For any  $\theta, \theta' \in \Theta$ ,  $\mathcal{E}(\theta) \cap \mathcal{E}(\theta') = \emptyset$ .

If assumption 1 holds,  $\sigma \in \mathcal{E}(\theta_0)$ ,  $\theta' \neq \theta_0$ , and H is chosen judiciously, then  $Q(\theta',\sigma) > 0$ : assumption 1 implies that  $\sigma \notin \mathcal{E}(\theta')$ , so that  $g(\boldsymbol{\xi},\nu,\sigma';\sigma,\theta') < 0$  for some  $(\boldsymbol{\xi},\nu,\sigma',\sigma)$ .<sup>10</sup>

<sup>&</sup>lt;sup>10</sup>To be more precise, we require that  $g(\boldsymbol{\xi}, \nu, \sigma'; \sigma, \theta') < 0$  on a set of positive H-measure for all  $\theta' \neq \theta_0$ . We can attach this condition to our definition of MPE. Given a measure  $\mu$  on the set of tuples  $(\boldsymbol{\xi}, \nu, \sigma')$ , say that  $(\sigma, \dots, \sigma)$  is a symmetric MPE if  $g(\boldsymbol{\xi}, \nu, \sigma'; \sigma, \theta_0) < 0$  with zero  $\mu$ -measure. Then choose H such that  $\mu$  is absolutely continuous with respect to H. If  $\theta' \neq \theta_0$ , assumption 1 implies that  $g(\boldsymbol{\xi}, \nu, \sigma'; \sigma, \theta') < 0$  with positive  $\mu$ -measure. This implies that  $g(\boldsymbol{\xi}, \nu, \sigma'; \sigma, \theta') < 0$  with positive  $\mu$ -measure, otherwise absolute continuity of  $\mu$  with respect to H would be violated.

Bajari et al. (2007) propose estimating the structural parameters of the model by minimizing a sample analog of (19). In particular, for some set of  $(\xi, \nu, \sigma')$  tuples, indexed by  $i = 1, \dots, n_I$ , they propose minimizing

$$\hat{Q}(\theta, \hat{\sigma}) := \frac{1}{n_I} \sum_{i=1}^{n_I} \left( \min \left\{ g(\boldsymbol{\xi}_i, \nu_i, \sigma_i'; \hat{\sigma}, \theta), 0 \right\} \right)^2$$

where  $\hat{\sigma}$  is the strategy profile estimated in a first step. Evaluating this objective requires estimates of the value function V under the estimated policies and under the deviations. Bajari et al. (2007) propose obtaining these estimates by forward simulation. As they note, linearity of flow profits significantly reduces the computational burden of forward simulation. Linearity implies that there exists a function  $\Lambda(\boldsymbol{\xi}, \nu; \sigma', \sigma)$  such that  $V(\boldsymbol{\xi}, \nu; \sigma', \sigma, \theta) = \Lambda(\boldsymbol{\xi}, \nu; \sigma', \sigma)\theta$ . Therefore, the forward simulation needs to be performed only once for each pair  $(\sigma', \sigma)$  to obtain  $\Lambda(\boldsymbol{\xi}, \nu; \sigma', \sigma)$ . Linearity of flow profits does apply to the Hashmi and van Biesebroeck (2016) model.

### 5 Monte Carlo Simulations

We now discuss the performance of the estimators discussed in Sections 3 and 4 for the model presented in Section 2.<sup>11</sup> We consider a rather data-rich environment, with data from 100 separate markets recorded for 40 periods. 5 firms compete in each market.<sup>12</sup> Firms have marginal cost parameters  $\theta_{c1} = 2.47, \theta_{c2} = 0$  – i.e. constant marginal cost  $mc = \exp(2.47)$ ; unobserved product quality goes from -1.4 to 1.4 in increments of .2. There is a substantial probability of quality downgrade shocks ( $\theta_{t1} = 0.547$ ), and the probability of a quality upgrading shock is increasing in own investment ( $\theta_{t2} = 0.062$ ) but decreasing (at a decreasing rate) in own quality level ( $\theta_{t3}, \theta_{t4} < 0$ ). Investment costs are convex ( $\theta_{x1}, \theta_{x2} > 0$ ) in investment and increasing in the 'shock' term ( $\theta_{x3} > 0$ ). We outline all parameters in Table 1.

We compare the performance of four estimators:

<sup>&</sup>lt;sup>11</sup>While we eventually intend to consider multiple parameterisations of the model, for the moment we only discuss one such parameterisation.

<sup>&</sup>lt;sup>12</sup>For comparison, Hashmi and van Biesebroeck (2016) aggregate data to have a single market with 14 firms for the 1982-2006 period. Ryan (2012) collected a total of 517 market-year pairs (an unbalanced panel of 27 markets over 19 years), with the number of firms in a market-year ranging from 1 to 20. We repeat the estimator comparison for a data structure akin to the one in Ryan (2012) in Appendix ??.

Table 1: Exercise Parameters

Parameter	Value		
Data Structure			
Number of Firms	5		
Number of Markets	100		
Number of Periods	40		
Number of Households	1.0e8		
Model			
State Space	-1.4:0.2:1.4		
Discount Factor	0.925		
Marginal Utility of Income	-0.222		
Marginal Cost Parameters	[2.47 0.0]		
Investment Cost Parameters	[2.625 1.624 0.5096]		
Transition Probability Parameters	[0.547 0.062 -0.884 -0.285]		
Recursive Estimator			
Number of II Simulations	5		
<b>BBL Estimators</b>			
BBL: Number of Inequalities	1000		
BBL: Number of Simulated Paths	1000		
BBL: Simulation Horizon	80		
BBL: Vector of Scalar Deviations	[0.9 0.95 1.05 1.1]		

This table reports parameters used in our Monte Carlo exercise. The parameters labeled BBL relate to our implementation of the BBL estimator. Number of inequalities is the number of equilibrium conditions included in the BBL objective. Number of simulated paths is the number of paths used in estimating value functions via simulation. Simulation horizon is how far the paths are simulated. The vector of scalar deviations defines the HvB deviations discussed in the text. The following set of parameters relate to the HvB model discussed above. Number of II simulations is the number of  $\nu$  draws per observed observation used in the recursive estimator. The number of markets and periods pertain to the size of the dataset used in the Monte Carlo simulations. State space is the set of possible qualities for a firm; the notation -1.4:0.2:1.4 indicates that quality can be as low as -1.4 and as high as 1.4, growing in increments of 0.2.

- 1. The estimator proposed in Section 3 (recursive estimator);
- 2. A BBL estimator that uses multiplicative shifts of the candidate policy function to compute deviations:  $\sigma'(\boldsymbol{\xi}, \nu) = \iota \sigma(\boldsymbol{\xi}, \nu)$  for  $\iota \in \{.90, .95, 1.05, 1.10\}$  (Hashmi and van Biesebroeck (2016)'s estimator);
- 3. A BBL estimator computing  $\sigma'(\boldsymbol{\xi}, \nu) = \sum_{k=1}^{B} \tilde{\gamma}_k \Psi_k(\boldsymbol{\xi_i})$ , where  $\tilde{\gamma} \sim N(\hat{\gamma}, \hat{\Sigma}_{\gamma})$  and  $\hat{\gamma}$ ,  $\hat{\Sigma}_{\gamma}$  are estimated from the data (BBL estimator);

4. An estimator that directly minimises the distance between the estimated policy function and the one implied by firms' Bellman equations, defined by

$$\min_{\theta \in \Theta} \sum_{\xi} \left( \int_{\mathbb{R}} T_{\theta,\hat{\sigma}}(\boldsymbol{\xi}, \nu) \phi(\nu) d\nu - \hat{\sigma}(\boldsymbol{\xi}) \right)^{2}$$
 (20)

(naïve estimator).<sup>13</sup>

Table 2 describes the performance of the four estimators. It lists true parameter values, along with estimate average and confidence intervals for the four estimators over 250 simulations.

Because the BBL and HvB estimators are defined by inequalities, it is in principle possible for them to return parameter interval estimates rather than point estimates. We allow for this possibility and present average lower and upper bound for each estimated set. In practice, we find these estimators always return point estimates.

In order to present confidence intervals that are sensible for both point- and setidentified parameters, we display the shortest intervals containing 95 percent of estimated intervals/points, as defined for example in Manski and Tamer (2002).

Of the four estimators, the recursive estimator evidently performs the best: averages are close to the true parameters, with small confidence intervals. BBL estimators and the naïve estimator display substantial bias and very large confidence intervals. Figures 1, 2, 3, and 4 present the distribution of parameter estimates for each algorithm; vertical dotted lines represent true parameter values. Recursive estimates are correctly centered around the true values. HvB and BBL estimators are centered around wrong values, displaying a bias that can be orders of magnitude larger than the parameter to be estimated. The finite sample bias of the naïve estimator is smaller than that of the BBL implementations, but it is still substantial compared to that of the recursive estimator.

<sup>&</sup>lt;sup>13</sup>This estimator is naïve in the sense that it tries to extend the intuition of Pesendorfer and Schmidt-Dengler (2008) to the case of continuous controls.

<sup>&</sup>lt;sup>14</sup>Aguirregabiria, Collard-Wexler, and Ryan (2021): "[...] in most applications of the BBL method, the relatively small set of alternative CCPs selected by the researcher does not provide enough moment inequalities to achieve point identification such that the BBL method provides set estimation of the structural parameters."

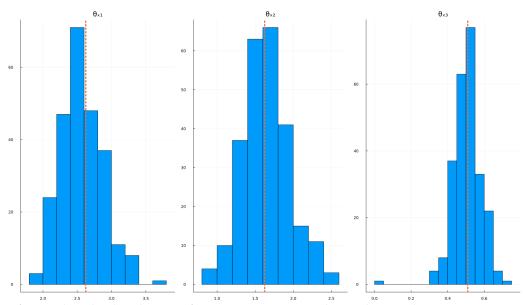

<sup>&</sup>lt;sup>15</sup>Because each inequality are linear in  $\theta$ , the entire list of inequalities defines a polyhedron. We first check whether such polyhedron is non-empty. If it is not, we compute parameter sets as the projections of the polyhedron on each parameter's axis. If it is, we minimise the BBL objective.

Table 2: Summary of Parameter Estimates

	Value	Recursive	BBL	HvB	Recursive Naïve
$\theta_{x1}$	2.625	2.579	[30.53, 30.53]	[0.0, 0.0]	12.43
		(2.123, 3.305)	(0.0, 82.166)	(0.0, 0.0)	(3.424, 18.761)
$\theta_{x2}$	1.624	1.646	[30.448, 30.448]	[3.221, 3.221]	0.643
		(1.082, 2.34)	(0.0, 47.149)	(1.972, 4.297)	(0.288, 2.612)
$\theta_{x3}$	0.5096	0.506	[4.48, 4.48]	[4.823, 4.823]	9.39
		(0.364, 0.649)	(0.0, 20.098)	(0.0, 18.998)	(6.614, 13.323)

This table summarizes the results of our Monte Carlo experiment. The first column shows the value of the parameters of the investment cost function in the data generating process. Each subsequent column shows the mean and shortest 95% interval for estimates across Monte Carlo replications. The column labeled "Recursive" shows the results of the estimator we propose in this paper. The column labeled "BBL" shows the results of the BBL estimator with random deviations. The column labeled "HvB" shows the results of the BBL estimator with HvB deviations. The column labeled "Recursive Naive" shows the results of the estimator defined by the program 20.

Figure 1: Recursive Estimator Parameter Estimates

This figure plots the distribution of parameter estimates obtained using the recursive estimator of section 3 over 250 Monte Carlo replications. The vertical dashed red line indicates the value of the corresponding parameter in the data generating process.

Figure 2: HvB Estimator Parameter Estimates

This figure plots the distribution of parameter estimates obtained using the BBL estimator with HvB deviations over 250 Monte Carlo replications. The vertical dashed red line indicates the value of the corresponding parameter in the data generating process.

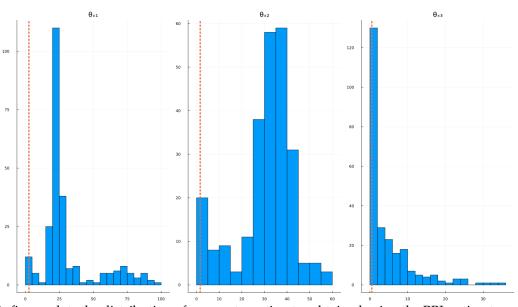

Figure 3: BBL Estimator Parameter Estimates

This figure plots the distribution of parameter estimates obtained using the BBL estimator with random deviations over 250 Monte Carlo replications. The vertical dashed red line indicates the value of the corresponding parameter in the data generating process.

Figure 4: Naïve Estimator Parameter Estimates

This figure plots the distribution of parameter estimates obtained using the estimator defined by the problem 20 over 250 Monte Carlo replications. The vertical dashed red line indicates the value of the corresponding parameter in the data generating process.

The relative performance of the different estimators is a consequence of the differences in the objective functions that define them. We illustrate this by analysing the shape of each objective function in a neighbourhood of the true parameters for a particular simulated dataset. To do so, we plot two-dimensional slices of the objective function by varying one parameter at a time while holding the others fixed at their true values. To render the shape of different objective functions comparable, we normalise objective values on the parameter grid by dividing each by the objective value at the true parameter.

Figures 5 to 8 display the results. Vertical lines represent true parameter values.

Figure 5 shows that the objective function of the recursive estimator features pronounced local convexity around each true parameter, with minimal distance between the local objective minimum and the objective value at the true parameter. This is reflected in the good performance of the estimator. The picture is very different for the HvB and BBL estimators: they are approximately flat around the true parameter, and zooming in reveals that they display no convexity at all for the considered grid – they are almost linear around the correct parameter values. This is consistent with the large bias displayed in Figures 2 and 3: the objective is convex around parameter values that are wrong by orders of magnitude.

Finally, objective plots for the naïve estimator are informative about its imprecision. Objective function minima are not far from the minima at the true parameter value (lower bias) for  $\theta_{x1}$ ,  $\theta_{x2}$ , but the naïve objective function is much less convex around local minima than the recursive objective function is. On the other hand, the objective function is evidently not centered around the true parameter objective value for  $\theta_{x3}$ .

Figure 5: Recursive Estimator Objective

This figure plots the value of the recursive estimator objective function varying one parameter at a time while holding the other two parameters fixed at their true values. Values are scaled by the value of the objective at the true parameters.

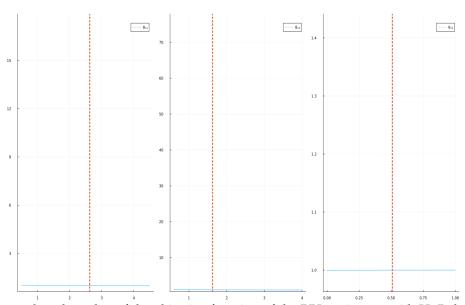

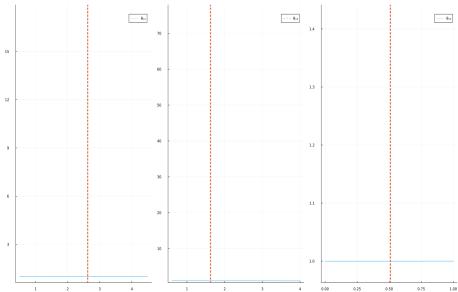

Figure 6: HvB Estimator Objective

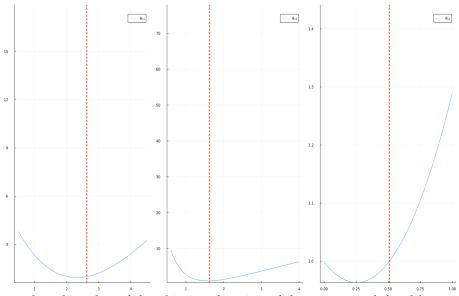

This figure plots the value of the objective function of the BBL estimator with HvB deviations varying one parameter at a time while holding the other two parameters fixed at their true values. Values are scaled by the value of the objective at the true parameters.

Figure 7: BBL Estimator Objective

This figure plots the value of the objective function of the BBL estimator with random deviations varying one parameter at a time while holding the other two parameters fixed at their true values. Values are scaled by the value of the objective at the true parameters.

Figure 8: Naïve Estimator Objective

This figure plots the value of the objective function of the estimator defined by program 20 varying one parameter at a time while holding the other two parameters fixed at their true values. Values are scaled by the value of the objective at the true parameters.

Table 3: Exercise Timings (250 Simulations)

Call	Average Time	Average Allocation
Overall	8-	8-
Preliminaries	36.1s	36.4GiB
Simulation	124ms	25.7MiB
Step 1: Estimating Transition Parameters	123ms	1.27MiB
Step 1: Estimating Policy Functions	41.8ms	18.9MiB
Computing $\hat{\sigma}(\boldsymbol{\xi}, \nu)$ and $P(\xi' \xi, \hat{\sigma}(\boldsymbol{\xi}, \nu))$	123ms	117MiB
Computing VF Covariates	39.4s	14.4GiB
Computing EVF Covariates	196ms	4.32MiB
Computing Projection Objects	19.0ms	21.0MiB
Step 2: Recursive Estimator	57.3s	23.3GiB
Step 2: Naive Estimator	309s	271GiB
Step 2: BBL Policy Covariates	18.1ms	14.6MiB
Step 2: BBL Estimator	3.71s	13.0MiB
Simulation	3.68s	2.19MiB
Optimisation	33.8ms	10.8MiB
Step 2: HvB Estimator	3.76s	11.9MiB
Simulation	3.75s	1.80MiB
Optimisation	9.06ms	10.1MiB

This table reports the computation time and memory allocation associated with each step in the computation of the four estimators discussed above. Note that the memory allocation reported here is not the amount of memory required to compute these estimators, but rather the total size of objects that are written to memory throughout the course of estimation. "Preliminaries" include the calculation of descriptors of flow profits, objects describing the state space of the game, and solving for a MPE. "Simulation" is the simulation of the data. "Computing VF Covariates" refers to the calculation of  $EV(\cdot)$  in Equation (13). "Computing Projection Objects" refers to the calculation of objects used in the implementation of the recursive estimator that need to be computed only once. The other items refer to the different estimators.

We conclude this section with an overview of the computational costs of each estimator. Table 3 displays run time and memory allocation for the different steps of our simulation, averaged over 250 runs. As expected Step 1 – shared by all the algorithms considered – is fast, as it only entails estimating transition parameters by maximum likelihood and policy function parameters by linear regression.

 $<sup>^{16}</sup>$ 'Preliminaries' are objects that only need to be computed once to set up multiple simulations.

On the other hand, there is substantial variation in the time and memory costs of various Step 2 algorithms. BBL-type estimators are the fastest, with both the HvB and BBL estimator taking less than 10 seconds between simulation and optimisation.<sup>17</sup> The recursive estimator is substantially slower: between computing the objects needed to form the objective (39s) and estimation (57s), the estimator takes approximately 1m35s to return an estimate. Estimation time will be increasing in the number of datasets generated for indirect inference, which we set to 5. Finally, the naïve estimator takes the most time of all, clocking at more than 5 minutes (with very substantial dispersion, not documented in the table). The reason for this substantial cost is that evaluation of its objective and gradient requires solving a large number of static optimisation problems, whereas the gradient of the recursive estimator is readily computed analytically (see Appendix B).

### 6 Conclusion

We have revisited the estimation of dynamic games with continuous controls. We note that the commonly applied inequality estimator of Bajari et al. (2007) does not fully exploit the structure of optimal policies and propose an estimator that does so. Our estimator combines two-step methods that are common in the estimation of dynamic models with indirect inference ideas. We conduct a Monte Carlo experiment based on an empirically-relevant model and find that the estimator we propose significantly outperforms available alternatives in terms of precision. Bajari et al. (2007) themselves propose an estimator that does use the structure of optimal policies. However, the empirical literature has converged to applying exclusively their inequality estimator. We hope that by providing clear implementation details and documenting the substantial advantages of fully exploiting the structure of the model, our contribution will steer the literature towards doing so whenever feasible.

<sup>&</sup>lt;sup>17</sup>In earlier drafts, we had found BBL-type estimators to be much slower. Substantial code optimization exponentially cut computation time.

# **Appendix A** Characterizing EV

This section derives equation (13). We start from equations (3) to (5), repeated here for the reader's convenience:

$$V_{j}(\xi_{j}, \boldsymbol{\xi}_{-j}, \nu) = \max_{x \in \mathbb{R}_{+}} \left\{ \pi(\xi_{j}, \boldsymbol{\xi}_{-j}) - c(x, \nu) + \beta \mathbb{E}_{\boldsymbol{\sigma}_{-j}} \left[ V_{j}(\xi'_{j}, \boldsymbol{\xi'}_{-j}, \nu' | \xi_{j}, \boldsymbol{\xi}_{-j}, x) \right] \right\}$$
(3)

where

$$\mathbb{E}_{\boldsymbol{\sigma}_{-j}}\left[V_{j}(\xi_{j}',\boldsymbol{\xi}_{-j}',\nu')|\xi_{j},\boldsymbol{\xi}_{-j},x\right] = \sum_{\boldsymbol{\xi}_{j}'} \sum_{\boldsymbol{\xi}_{-j}'} \int_{\nu} V_{j}(\xi_{j}',\boldsymbol{\xi}_{-j}',\nu') dF(\nu') P_{-j}(\boldsymbol{\xi}_{-j}'|\boldsymbol{\xi};\boldsymbol{\sigma}_{-j}) P_{j}(\xi_{j}'|\xi_{j},x)$$

$$\tag{4}$$

and

$$P_{-j}(\boldsymbol{\xi}'_{-j}|\boldsymbol{\xi};\boldsymbol{\sigma}_{-j}) = \prod_{k \neq j} P(\xi'_k|\boldsymbol{\xi};\sigma_k) = \prod_{k \neq j} \int_{\nu_k} P(\xi'_k|\xi_k,\sigma_k(\boldsymbol{\xi},\nu_k)) dF(\nu_k) .$$
 (5)

Plugging in the equilibrium policy into the right-hand side of (3) and using (4), (5), and the definition of  $EV(\xi)$ , we have

$$V(\boldsymbol{\xi}, \nu) = \pi(\boldsymbol{\xi}) - c(\sigma(\boldsymbol{\xi}, \nu); \boldsymbol{\theta}_x) + \beta \sum_{\boldsymbol{\xi'}} EV(\boldsymbol{\xi'}) \prod_{k \neq j} \mathbb{P}(\xi'_k | \boldsymbol{\xi}) \mathbb{P}(\xi'_j | \xi_j, \sigma(\boldsymbol{\xi}, \nu)) .$$

Integrating both sides of this equation yields

$$EV(\boldsymbol{\xi}) = \pi(\boldsymbol{\xi}) - \int c(\sigma(\boldsymbol{\xi}, \nu); \boldsymbol{\theta}_x) dF(\nu) + \beta \sum_{\boldsymbol{\xi'}} EV(\boldsymbol{\xi'}) \prod_{k \neq j} \mathbb{P}(\xi'_k | \boldsymbol{\xi}) \int \mathbb{P}(\xi'_j | \xi_j, \sigma(\boldsymbol{\xi}, \nu)) dF(\nu)$$

$$= \pi(\boldsymbol{\xi}) - \boldsymbol{\theta}_x \cdot \int w_x(\sigma(\boldsymbol{\xi}, \nu), \nu) dF(\nu) + \beta \sum_{\boldsymbol{\xi'}} EV(\boldsymbol{\xi'}) \prod_{k=1}^N \mathbb{P}(\xi'_k | \boldsymbol{\xi}) ,$$

where  $w_x(x,\nu) = \begin{bmatrix} x & x^2 & \nu x \end{bmatrix}$  is the vector of cost covariates, and the second equality uses the linearity of the cost of investment and the definition of  $\mathbb{P}(\xi_j' \mid \boldsymbol{\xi}) = \int \mathbb{P}(\xi_j' \mid \xi_j, \sigma(\boldsymbol{\xi}, \nu)) dF(\nu)$ . Therefore,

$$EV(\boldsymbol{\xi}) = \boldsymbol{W}(\boldsymbol{\xi}; \boldsymbol{\pi}, \sigma) \cdot [1, -\boldsymbol{\theta_x'}]' + \beta M(\boldsymbol{\xi}, \boldsymbol{P}) \boldsymbol{EV}$$

where  $W(\xi; \pi, \sigma)$  is the expectation of flow-profit covariates given  $\xi$ , as defined in equation (14), and  $M(\xi, P)$  is the  $\xi$ -th row of the matrix M(P) defined in equation (15).

Stacking the last equation for all  $\xi$  and solving for EV gives equation (13). To see that  $I - \beta M(P)$  is indeed invertible, assume it is not. Then there exists  $x \in \mathbb{R}^{|\Xi|}$  such that  $[I - \beta M(P)]x = 0$ , or  $x = \beta Mx$ . This implies  $||x||_{\infty} = ||\beta Mx||_{\infty}$ . However, letting  $(Mx)_i$  denote the i-th coordinate of Mx, we have

$$|(\boldsymbol{M}x)_i| = \left| \sum_{j=1}^{|\Xi|} M_{ij} x_j \right| \le \sum_{j=1}^{|\Xi|} M_{ij} |x_j| \le ||x||_{\infty} \sum_{j=1}^{|\Xi|} M_{ij} = ||x||_{\infty},$$

where we have used that M is a stochastic matrix. Therefore  $||x||_{\infty} = ||\beta Mx||_{\infty} = \beta ||Mx||_{\infty} \leq \beta ||x||_{\infty}$ , a contradiction.

# **Appendix B** The Gradient of $Q(\theta)$

We have

$$\nabla Q(\theta) = 2[\hat{\boldsymbol{\lambda}}(\theta) - \hat{\gamma}]' W_{(k+1)\times(k+1)} D_{\theta} \hat{\boldsymbol{\lambda}}(\theta)$$

where  $D_{\theta}\hat{\lambda}(\theta)$  is the derivative (i.e., the Jacobian) of  $\hat{\lambda}(\theta)$  and we have made the dimensions explicit for clarity. The symbols k and J represent, respectively, the number of covariates in the empirical policy function and the number of structural parameters to be estimated. These objects have dimension (k+1) rather than k because we include the estimated standard deviation in our objective function.

From the above, all that is left to calculate is  $D_{\theta} \hat{\lambda}(\theta)$ . Remember that  $\hat{\lambda}(\theta) = (\hat{\lambda}_1(\theta), \dots, \hat{\lambda}_k(\theta), S_{\zeta}(\theta))$ . Therefore

$$D_{\theta} \hat{\boldsymbol{\lambda}}(\theta) = \begin{pmatrix} D_{\theta} \hat{\boldsymbol{\lambda}}(\theta) \\ {}^{k \times J} \\ \nabla_{\theta} S_{\zeta}(\theta) \end{pmatrix}$$

The object  $\hat{\lambda}(\theta)$  is an OLS estimate, and thus satisfies

$$(X'X)\hat{\lambda}(\theta) = X'T_{\theta}(\hat{\sigma})$$

where *X* is the matrix of features

$$X = \begin{pmatrix} \psi_1(\xi_1) & \dots & \psi_k(\xi_1) \\ \vdots & \ddots & \vdots \\ \psi_1(\xi_N) & \dots & \psi_k(\xi_N) \end{pmatrix}$$

and<sup>18</sup>

$$T_{\theta}(\hat{\sigma}) = \begin{pmatrix} T_{\theta}(\hat{\sigma})(\xi_1, \nu_1) \\ \vdots \\ T_{\theta}(\hat{\sigma})(\xi_N, \nu_N) \end{pmatrix} ,$$

where  $T_{\theta}(\hat{\sigma})(\xi_i, \nu_i)$  is the optimal level of investment when the parameters are  $\theta$ , future behavior is given by  $\hat{\sigma}$ , and the state is  $(\xi_i, \nu_i)$ . Therefore,

$$(X'X)D_{\theta}\hat{\lambda}(\theta) = X'D_{\theta}T_{\theta}(\hat{\sigma}) \tag{21}$$

where

$$D_{\theta}T_{\theta}(\hat{\sigma}) = \begin{pmatrix} \nabla_{\theta}T_{\theta}(\hat{\sigma})(\xi_{1}, \nu_{i}) \\ \vdots \\ \nabla_{\theta}T_{\theta}(\hat{\sigma})(\xi_{N}, \nu_{N}) \end{pmatrix}$$

By the Implicit Function Theorem, the gradients in this matrix are given by

$$\nabla_{\theta} T_{\theta}(\hat{\sigma})(\xi_{i}, \nu_{i}) = -\left[\frac{\partial f}{\partial x}(x^{*}, \xi_{i}, \nu_{i}; \theta, \hat{\sigma})\right]^{-1} \nabla_{\theta} f(x^{*}, \xi_{i}, \nu_{i}; \theta, \hat{\sigma})$$

where  $x^* = T_{\theta}(\hat{\sigma})(\xi, \nu)$  and  $f(x, \xi, \nu; \theta, \hat{\sigma})$  is the investment first-order condition. We can then solve for  $D_{\theta}\hat{\lambda}$  from equation 21.

Next, we need  $\nabla_{\theta} S_{\zeta}(\theta)$ . We have

$$S(\theta) = \left\{ \frac{1}{n-k} \sum_{i=1}^{n} [T_{\theta}(\hat{\sigma})(\xi_i, \nu_i) - x(\xi_i)' \hat{\lambda}(\theta)]^2 \right\}^{\frac{1}{2}}$$

where  $x(\xi_i) := (\psi_1(\xi_i) \dots \psi_k(\xi_i))'$ . Therefore,

$$\nabla_{\theta} S_{\zeta}(\theta) = \frac{1}{2} \{\cdot\}^{-\frac{1}{2}} \times \frac{2}{n-k} \sum_{i=1}^{n} [T_{\theta}(\hat{\sigma})(\xi_{i}, \nu_{i}) - x(\xi_{i})'\hat{\lambda}(\theta)] \{\nabla_{\theta} T_{\theta}(\hat{\sigma})(\xi_{i}, \nu_{i}) - \nabla_{\theta} [x(\xi_{i})'\hat{\lambda}(\theta)] \}$$

$$= \frac{1}{S_{\zeta}(\theta)(n-k)} \sum_{i=1}^{n} [T_{\theta}(\hat{\sigma})(\xi_{i}, \nu_{i}) - x(\xi_{i})'\hat{\lambda}(\theta)] \{\nabla_{\theta} T_{\theta}(\hat{\sigma})(\xi_{i}, \nu_{i}) - \nabla_{\theta} [x(\xi_{i})'\hat{\lambda}(\theta)] \}$$

<sup>&</sup>lt;sup>18</sup>We draw the  $\nu_i$  shocks once and store them in memory so that all parameter values use the same  $\nu_i$  shocks.

The first gradient in these expressions has already been characterized. The second gradient is

$$\nabla_{\theta}[x(\xi_i)'\hat{\lambda}(\theta)] = x(\xi_i)'D_{\theta}\hat{\lambda}(\theta)$$

and  $D_{\theta}\hat{\lambda}(\theta)$  has just been characterized.
